HYDROGEOLOGIC DATA FROM FOUR LANDFILLS IN NORTHEASTERN ILLINOIS

G. M. Hughes, R. A. Landon, and R. N. Farvolden

INTRODUCTION

Methods of drilling, sampling, and analysis used in an investigation of four landfills in northeastern Illinois and the geologic and geochemical data derived from the study are presented in this report. The investigation, undertaken to determine the hydrogeologic conditions and effects of waste disposal at four sites in representative glaciated terrains, is being carried on by the Illinois State Geological Survey, the University of Illinois, and the State Department of Public Health under U. S. Department of Health, Education and Welfare Demonstration Grant No. 5-D01-01-00006-02. The contents of this note are taken from our report entitled "Hydrogeology of Solid Waste Disposal Sites in Northeastern Illinois," which we submitted to the U. S. Department of Health, Education and Welfare on July 1, 1968.

Location of the four sites is shown in figure 1. All data in the tables refer to sampling points, the locations of which are shown on maps of the DuPage County (fig. 2), Winnetka (fig. 3), Elgin (fig. 4), and Woodstock (fig. 5) landfills.

The data include piezometer and sampling points (table 1), sample description logs (table 2), sieve analyses of representative earth materials (table 3), clay mineral analyses (table 4), chemical analyses of leachate and ground water associated with the landfills, made by the State Department of Public Health (table 6) and by a commercial laboratory (table 7), and results of neutron activation analyses for selected elements (table 8).

OPERATIONS AND GEOLOGIC CONDITIONS AT THE LANDFILL SITES

Filling at the DuPage County site was started in September 1952 and completed in November 1965. The site is reported to have been operated as a sanitary landfill, although refuse was probably deposited below the top of the zone of saturation and ponds are present in wet weather on the fill surface.

The site occupies a poorly drained lowland adjacent to Kress Creek on a flat area between the Minooka Moraine on the west and the West Chicago

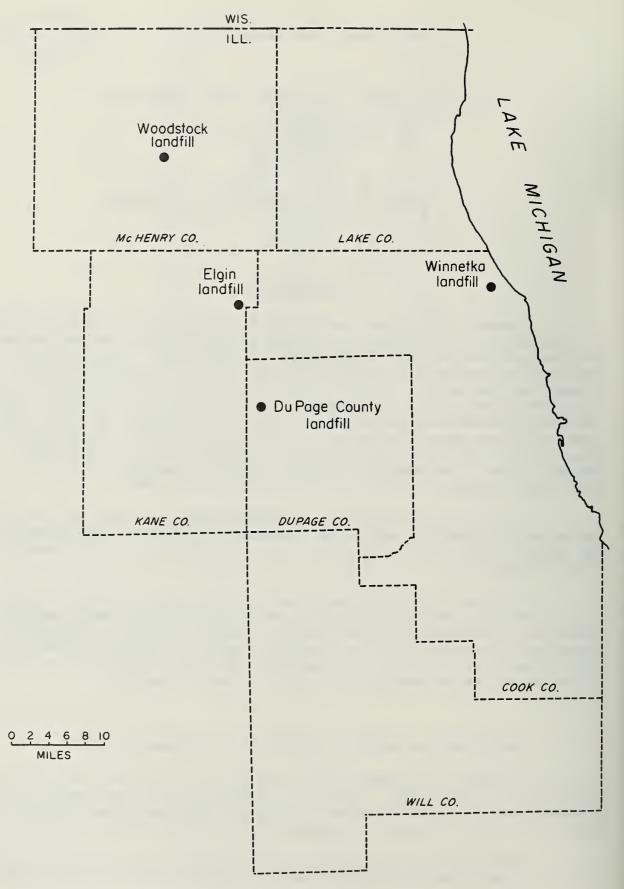

Fig. 1 - Solid waste disposal sites studied in northeastern Illinois.

Moraine on the east. The 75 feet of glacial drift under the site consists of a surficial sandy material and several tills. The sandy silt to silty sand at the surface is as much as 21 feet thick, but it thins toward the margins of the landfill. The upper till is a clayey silt till ranging from 5 to 25 feet thick. The middle, sandy silt till is 12 to approximately 20 feet thick and the eastern half of the site generally is underlain by l_2^1 to 5 feet of sand and fine gravel. The lower unit, a silt till, is 20 feet thick. The bedrock consists of fractured dolomite of Silurian age that is a major aquifer in the area.

Filling at the Winnetka site was begun in January 1947 and is continuing at present. The site is operated as a sanitary landfill, although refuse is deposited below the top of the zone of saturation and ponds are present in wet weather on the fill surface.

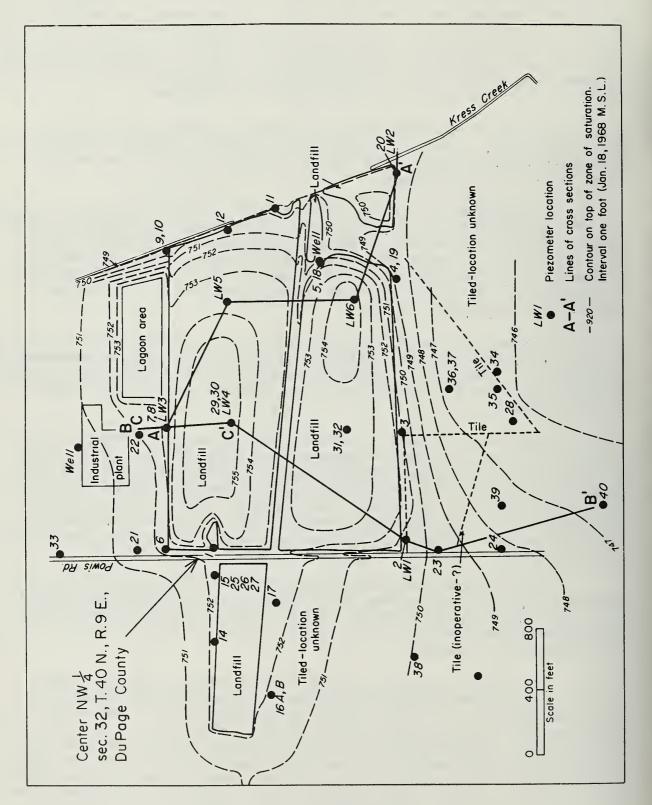

The landfill is on a flat area adjacent to the Skokie River. Several feet of soil and fill and 5 to 11 feet of sandy clay and silt alluvium form the surficial deposits. The drift is about 110 feet thick and consists mostly of silty clay tills that become more sandy and stony with depth. Sand and silt stringers 6 inches to 2 feet thick and of small lateral extent are interbedded with the till at the base of the drift. The bedrock consists of fractured dolomite of Silurian age.

Filling was begun at the Elgin site in 1948, and the site was operated as an open, burning dump until 1964, when sanitary landfilling was commenced; it is continuing. Probably no appreciable quantities of refuse have been deposited below the top of the zone of saturation, and there is little if any ponding on the fill surface.

The site is adjacent to the Fox River on the site of a former gravel pit operation. Two to 3 feet of clayey silt to sandy silt topsoil may cover the drift. The drift is about 60 feet thick and consists of 20 feet of sand and gravel (10 feet have been removed by gravel operation), nearly 40 feet of sandy silt tills, and 2 to 5 feet of basal sand and gravel. A thin layer of fractured dolomite of Silurian age forms the bedrock. Dolomite and shale of the Maquoketa Group lie beneath the Silurian dolomite and crop out immediately west of the site.

Filling at the Woodstock site was begun in 1940, and the site was operated as an open, burning dump until 1965. At that time sanitary landfilling was commenced and is continuing. In the early stages of filling, refuse was deposited below the top of the zone of saturation. Ponding occurs on the fill surface in wet weather.

The landfill occupies a swampy lowland and slope adjacent to the southern margin of the West Chicago Moraine. The southern two-thirds of the site is covered by 5 to 19 feet of peat and nonorganic silt. Several feet of silty clay soil, which becomes sandy toward the northern end of the site, may cover the peat. The thick drift consists of a surficial sand and gravel up to 19 feet thick, 245 feet of till and interbedded sand and gravel, and basal sand and gravel. The upper till is a silty clay that reaches a maximum thickness of 20 feet but thins over topographic lows. The lower tills change from sandy silt to silty sand with increasing depth. Sand and gravel deposits commonly 5 or more feet thick are interbedded with these tills. The bedrock consists of a thin layer of fractured Silurian dolomite overlying dolomite and shale of the Maquoketa Group.

DRILLING, MATERIAL SAMPLING, AND PIEZOMETER AND WELL POINT INSTALLATION

Installation Procedure

Most of the drilling for the landfill investigation was done under an hourly contract with Layne-Western Company, Aurora, Illinois, but a substantial number of the shallow borings were made by project personnel with a portable Mobile Minuteman auger drill loaned by the University of Illinois Water Resources Center. A total of 3459 feet was bored and 167 piezometers and sampling points installed. Pertinent data regarding these borings are given in table 1.

The contract drilling program proceeded as follows. A rotary rig, in most cases a Franks FA 54 with bentonite or natural drilling fluid, drilling a 4 3/4-inch to 7 7/8-inch hole was used first at each site to establish the sequence of materials. Piezometers were then installed to get preliminary information on ground-water elevations. Samples of drill cuttings were collected at the mud tank and these, with information from the driller on the drilling characteristics of the materials and from a Widco electrical resistivity drill hole log, provided adequate data for the selection of points at which the piezometers were to be set.

The next series of contract borings used the hollow stem auger method and generally a Mobile B 61 auger rig boring a 10-inch hole. These holes were limited to a depth of approximately 55 feet. Split-spoon samples were taken inside these augers to get a more precise definition of the character of the materials by visual and laboratory methods.

Additional contract borings were made by using one of the above methods, and in one case the air-drilling method was used.

Three types of piezometers were used:

- 1) A 24 x 1½-inch No. 10 well screen (3' total length) on 1½-inch plastic pipe.
- 2) A 6 x 1½-inch No. 10 suction strainer on 1½-inch plastic pipe.
- 3) Porous plastic $1\frac{1}{2} \times 18$ -inch on 3/8-inch ID (internal diameter) polyethylene tubing.

The well screen and suction strainer were set in materials considered permeable enough to produce reliable water samples for quality analyses. The plastic piezometer tip was used only in relatively impermeable materials. The suction strainer was used only in holes less than 20 feet deep.

The installation of screened piezometers in rotary borings proceeded in the following manner. After the boring was made, the screen attached to the $1\frac{1}{4}$ -inch plastic pipe was installed in the hole at the proper

depth. If the screen were to be set above the bottom of the hole, backfill was added until a solid bottom was present at the proper depth. The bore hole was then back-flushed, through the plastic pipe and screen, until returns were relatively clear. An average of 200 gallons of water was necessary to flush a 100-foot hole. Sand* was then poured into the boring or washed down a half-inch pipe to approximately 1 foot above the screen. The latter method was most efficient. Next, a seal was installed above the sand by one of the following methods:

- 1) A bentonite slurry was pumped down a half-inch pipe in the annulus. If the slurry is too thick, backfill will not settle and subsequent piezometers will sink.
- 2) Dry bentonite pellets or granules were poured down the annulus. This method was used only in shallow borings, as the bentonite tended to bridge.
- 3) Clay cuttings and mud returns from the rotary drilling were poured down the annulus.

The hole was then backfilled with cuttings or a fill, sand, and cuttings mixture to the approximate base of the next piezometer, and the foregoing procedure was repeated. Up to six piezometers were installed in one boring. In holes subject to caving, two piezometers were hung in the hole at the same time so that if caving occurred the hole could be flushed through both piezometers.

Installations drilled by the hollow stem auger method, in which screened piezometer tips were used, were made in a similar manner except that the piezometer was installed inside the hollow stem augers. The augers were raised a little at a time to allow placement of the sand around the piezometer tip and the seal. The porous plastic piezometer tips were also installed through a hollow stem auger and dry bentonite pellets used as a seal.

In the boring made by the air-drilling method, casing was used to shut out any shallow water and the hole advanced dry to the first permeable zone below the casing. A screened piezometer was installed opposite this zone, sand was blown down around the point, and dry bentonite blown down above the sand to form a seal. Dry bentonite coats and seals the sides of the boring, making multiple installations less practical. This type of installation can be used if no appreciable quantities of water are encountered.

Borings made with the portable Mobile Minuteman power auger were generally less than 15 feet deep. Screened piezometers were installed in these borings with and without flushing. Seals were installed at land surface to prevent vertical leakage and occasionally emplaced at depth by dropping dry bentonite down the annulus of the bore hole.

^{*} Commercially bagged silica sand (St. Peter Sandstone, with 60% and 30% retained on U. S. sieves 30 (0.589 mm) and 40 (0.417 mm) mesh, respectively) was used in most contracted borings. Local sand was used on some shallow borings.

Polyethylene tubing (3/8-inch ID) with cork mounted around one end was used to reduce the diameter of the standpipes in screened piezometers when it was found that these piezometers had been set in materials with low permeability and were not sensitive enough. The cork and tubing were inserted within the 1½-inch plastic pipe with a half-inch metal pipe to a point just above the screen. Dry bentonite was placed in the annulus between the 1½-inch plastic pipe and the 3/8-inch ID tubing after the half-inch metal pipe was removed. This method of increasing piezometer sensitivity was generally used in holes less than 20 feet deep, but it also was used in one hole 225 feet deep.

Evaluation of Installation Procedure

While the foregoing methods of installing piezometers are relatively inexpensive, it is difficult to install adequate seals between units, and these seals leaked in a number of instances. Leakage was established by adding or removing water from a suspect piezometer and noting changes in water level in adjacent piezometers in the same boring. Those units in which appreciable leakage could be established are as follows: (1) DuPage County landfill - LW 3B to surface sand; (2) Elgin landfill - between LW 4A and B; LW 5A and B; LW 7A and B; (3) Winnetka landfill - LW 1A,B,C, and D; LW 2C and D; LW 3B,C, and D; LW 4D and E; LW 7A,B, and C; LW 9A and B; (4) Woodstock landfill - LW 1B and C; LW 2B and C; LW 3A,B, and C. The leakage appears to be decreasing as the backfill in the borings compacts. The major problem arising from this leakage is in obtaining reliable water quality data.

WATER LEVEL MEASUREMENTS

After each piezometer had been pumped and developed, water level measurements were taken to determine whether it had stabilized and to determine its sensitivity. Measurements for this purpose were carried out at weekly or shorter intervals, depending on rainfall and other factors, until sufficient data had been gathered. In cases where the piezometer response time was very slow, water was added or removed to stabilize the unit. The standpipe diameter of most of the piezometers with slow response time was reduced in the fall of 1967.

After each piezometer had been stabilized, routine measurements were made at monthly intervals to determine seasonal changes in water levels. Additional measurements were made at shorter intervals after rain had fallen or the units had been pumped and sampled. Rainfall at each site was also measured with the piezometers, using a nonrecording gauge.

In the early fall of 1967, a recording rain gauge and a recording barometer were installed at the DuPage County site, in conjunction with three water level recorders equipped with Keck water level sensing devices. The recorders determined the relative effects of precipitation and barometric changes on water levels and aided in evaluating the routine measurements. The water level recorders were usually set in the same nest on holes of different depths, and eight-day charts were generally used.

SAMPLE DESCRIPTIONS

Following are sample logs from each of the contracted borings made in this investigation. In nests where separate borings were used for each piezometer, a composite log is given.

PUMPING AND SAMPLING PROCEDURES AND QUALITY ANALYSES

General Procedure

After each piezometer or sampling point was installed, it was developed and pumped with a windmill pump jack, a contractor's pump, or an air compressor. For those wells pumped with the pump jack, a plastic seat had been installed with the well screen, into which a ball bearing was dropped to serve as a foot valve. The pipe was used as the cylinder. The ball bearing was removed by a magnet after pumping had been completed. This initial pumping was continued until the water was clear or the chloride content became constant, and measurement was made in the field with a Hatch kit.

Samples were taken after the fluid had been exchanged at least twice in the screen and standpipe. This was done with the pump jack, contractor's pump, air compressor, or a bailer, depending on the depth, water level, and capacity of the particular point. The samples were usually collected with a rinsed bailer, put in mason jars, and sent immediately to the laboratory for analysis. No special precautions were taken to avoid loss of gases or to impede biologic activity during transportation to the laboratory.

Comments on the Results of Analyses

Considerable variation appeared in the results of the quality analyses that seemed to be unrelated to the distance of the leachate from the landfill or the age of the landfill. Three types of variations were noted.

 Samples taken from adjacent borings, with depth variations as little as 4 feet and not separated by any apparent permeability barrier, were consistently different. The shallower boring had as much as 50 percent fewer total dissolved solids than the deeper boring.

- 2) Samples taken on successive weeks from the same boring differed.
- 3) Samples taken before and after exchanging the water in the sampling point differed in constituents such as chlorides.

This variability, combined with the errors inherent in the sampling and analytical procedures made it impossible to calculate the amount of dissolved solids adsorbed during travel through specific types of materials. The data were, however, adequate for definition of the envelope of dissolved solids around each fill.

Biologic contaminants were not investigated as this would have involved chlorinating the sampling points and a more refined sample collection procedure.

Quality Analysis by the Illinois State
Department of Public Health

Table 5, prepared by the Illinois State Department of Public Health, lists the procedure used for the various analyses and the precision of these methods. The table appears on the next page.

QUALITY ANALYSES BY A COMMERCIAL LABORATORY

Table 7 shows a selection of more complete analyses run by Allied Laboratories, Chicago, Illinois. These samples were taken to the laboratory the day they were collected. Analytical methods used are from "Standard Methods for the Examination of Water and Waste Water" (American Public Health Association et al., 1965) and are listed below, with appropriate page references to that book.

pH - Glass electrode method (Beckman pH meter) - page 226

Iron - Tripyridine method - page 159

Bicarbonate ("M" alkalinity) - Titration with methyl orange - page 48

Chloride - Argentometric method - page 86

#### NEUTRON ACTIVATION ANALYSES

Neutron activation analyses were run by R. R. Ruch of the Illinois State Geological Survey on water samples from the studied fills on two occasions. The results of these analyses are listed in table 8.

The first samples were collected at the DuPage County landfill and analyzed in February 1967. When high bromine values were found in samples MM 2 and MM 29, we collected additional samples from all four fills in December 1967. At the suggestion of the U. S. Department of Public Health, selenium determinations were also made on these samples.

TABLE 8 - RESULTS OF NEUTRON ACTIVATION ANALYSES*

February	1967
----------	------

Sampling point	Br (ppm)	Na (ppm)	Cl (ppm)	Mn (ppm)	Comments
DuPage LW 3C	<0.09	7.6	2.1	0.12	Interbedded sand
DuPage LW 2B	<0.11	16	2.4	0.04	Interbedded sand
DuPage MM 2	6.2	187	262	≤0.01	Immediately south of fill in surficial sand
DuPage MM 29	13.6	875	1150	≤0.03	Below fill in surficial sand

#### December 1967

Sampling point	Br (ppm)	Se (ppm)	Na/Br	Comments
Winnetka MM 10 Winnetka LW 1E Elgin LW 5B Elgin LW 1C	3.6 [†] 11 3.6 [†] 1.9	<0.3	95 69 115 115	Point within refuse Point at base of refuse Sand and gravel below refuse Surficial sand east of fill beside Fox River

^{*} Irradiated for one hour in Triga reactor in January 1967. No long-lived radioactivity detected after two weeks.

### LANDFILL GASES

Gas from MM 30 at the DuPage County landfill was analyzed for  $CO_2$  (27.3%),  $O_2$  (0.2%),  $N_2$  (1.0%), and methane (71.5%). Analysis results were similar to those of landfill gases from California (Engineering-Science Inc., 1965)†but had a higher methane content than is common in that area. The methane in the gas presents an explosion hazard. The presence of carbon dioxide will raise the ground-water hardness.

[†] Average of duplicate runs. Estimated accuracy + 25% relative value.

^{* &}quot;In Situ Investigation of Movements of Gases Produced from Decomposing Refuse": Ann. Rept. 3, Calif. Water Quality Control Poard, Eng.-Sci. Inc., Arcadia, Calif.
